January 2023

Abstract

Summed many years of work at Pulkovo, the orbits of 67 wide pairs of visual double and multiple stars (included in 64 systems) which were obtained by the Apparent Motion Parameters (AMP) method are presented. This short arc determination orbit method is based on the most reliable astrometric and astrophysical data corresponding to one instant of time. The rest of the observations accumulated in the world serve to control the quality of the orbit and refine some parameters. All early determined AMP-orbits were compared with new observations, some of them were recalculated, new ones were added. For the stars of Pulkovo program of observations with a 26-inch refractor, the Gaia DR2 data were analysed. Based on these data, the orbits of 16 stars were calculated. In 20 cases from 67, the quasi-instant motion according to the Gaia DR2 data at the instant 2015.5 contradicts the motion according to all-world observations. A possible reason is the presence of inner subsystems. The orientation of the obtained orbits in the galactic coordinate system is also given.

Introduction

Double stars were first discovered by William Herschel at the end of the 18th century. In the 19th and 20th centuries, they were actively discovered by John Herschel, Wilhelm and Otto Struve, Paul Couteau and many other researchers. For stars with orbital periods of no more than 100-200 years, reliable orbits were determined, which made it possible to determine the masses of stars and derive fundamental laws relating the masses, spectra, luminosities and parallaxes of stars.

Wide, slowly circulating binary and multiple stars have been deprived of the attention of researchers, since from the moment of their discovery to the present time, observations cover a small arc of the orbit. However, such stars may turn out to be outer pairs of open or not yet discovered multiple systems. Namely, towards multiple systems, the components of which are being discovered more and more, the interest of researchers has now shifted - see works (Hale, 1994; Agati et al., 2015; Tokovinin, 2021). Their study ultimately carries information about star formation and the dynamic evolution of subsystems in our Galaxy. Therefore, the problem of determining the orbits of poorly studied wide binary stars remains relevant.

Observations of double stars have been a traditional theme of the Pulkovo Observatory since its opening in 1839. Therefore, when a 26-inch refractor appeared in Pulkovo after the Great Patriotic War, the priority task was to resume observations of wide binary stars in accordance with the capabilities of this telescope ($\rho > 3''$).

Especially for determining the orbits of such stars, the Apparent Motion Parameters method (AMP) was completed, see (Kiselev, Kiyaveva, 1980). This method was previously used to determine the orbit of an artificial satellite of the Earth from one photograph with many exposures (Kiselev, Bykov, 1973).

1 Application of the AMP-method

The AMP- method is designed to determine the initial orbits of wide visual binaries with a long period of revolution in position and velocity at one point in time based on the results of observations obtained by various available methods. These are the parameters of the apparent relative motion (AMPs) at one instant T_0 : the distance between the components (ρ), the position angle (θ), the visible relative motion (μ) and the position angle direction of the visible motion (ψ), as well as the radius of curvature (ρ_c). The most accurate AMPs are obtained from homogeneous observations (basis) made with a single telescope to eliminate instrumental systematic errors (see, e.g., series of photographic observations with a 26-inch refractor of the GAO RAS for 1957–2007: (Kiselev et al., 2014; Izmailov et al., 2016)).

In addition, the following data are necessary. They are: the parallax p_t (to relate linear and angular quantities), the relative radial velocity of the components $\Delta V_r = V_{rB} - V_{rA}$ (km/s), obtained from spectroscopic observations (to calculate the space velocity vector of the satellite relative to the main star), and an estimate of the sum of the masses of the components ΣM , according to the data on physical properties of these stars.

If it is possible to determine all five parameters, including the radius of curvature, then the distance between the components r in astronomical units can be calculated by the formula:

$$r^3 = k^2 \frac{\rho \rho_c}{\mu^2} |\sin(\theta - \psi)| \quad (1)$$

where $k^2 = 4\pi^2 \Sigma M$ is dynamic constant if distance is measured in au, time in years, mass in M_\odot .

Then we get two position vectors that correspond to the position of the secondary component symmetrically with respect to the picture plane, and, consequently, two orbits ($\pm\beta$). Here β is the angle between the spatial position of the satellite and its projection on to the picture plane, which can be calculated by the formula:

$$\beta = \pm \arccos(\rho/(p_t r)) \quad (2)$$

Sometimes, in agreement with the entire series of observations (see *Washington Double Star Catalog* — WDS, Mason et al. (2016)) one can choose one solution.

If the radius of curvature cannot be determined, then the distance between the components, we obtain according to the condition necessary for an elliptical orbit:

$$\frac{\rho}{p_t} \leq r < \frac{2k^2}{v^2}, \quad (3)$$

where v is the modulus of spatial velocity in au/year. In this case, we get a family of orbits. Each orbit of the family is characterized by the angle β .

If it is impossible to estimate the radius of curvature from a short arc of homogeneous observations, but the entire series of available observations reflects a nonlinear elliptical motion, then a more correct orbit can also be chosen from the family in agreement with the entire series of observations.

In order to obtain high-accuracy AMPs, at the Pulkovo Observatory much attention was paid to obtaining a homogeneous long-term series, from which the relative motion is determined more confidently. However, for some stars it was necessary to break the homogeneity and use additional observations from the WDS catalog.

The AMP orbits for the two stars included in this work (HIP 12706 and HIP 33287) required minor corrections and were refined using the differential correction method using Tokovinin's ORBITX program (Tokovinin, 1992). For these stars, Table 2 compares the AMPs obtained using the basis indicated in the table and the AMP ephemeris corresponding to the orbits refined using the ORBITX program.

Sufficiently accurate radial velocities are not available in the literature for all the stars in our program. Sometimes this parameter also had to be selected in agreement with the observations. Then the longitude of the ascending node and the longitude of the periastron from the node are determined with an accuracy of up to 180° and the ephemeris of the orbits in the projection onto the picture plane coincide. The remaining parameters remain the same, but the orientation of the orbital plane in the Galaxy changes. Thus, for the stars presented in this paper, we obtain 1, 2, 4 solutions or a family of orbits.

For the initial estimation of the sum of the masses of the components, we used the "mass-spectrum-luminosity" ratio according to the handbook (Allen, 1999) and data from the WDS catalog. However, there are no spectral types for many stars in the WDS catalog. Therefore one had to use different sources, which do not always give an unambiguous result. At present, the best way to get mass estimates is to use evolutionary track diagrams that link color index and magnitude (Girardi et al., 2000; Bressan et al., 2012).

Since most of the components of visual binaries in our program turned out to be spectroscopic binaries, data on them are contained in the Tokovinin *Catalog of Multiple Stars* — MSC, (Tokovinin, 2018). Nevertheless, in some cases, our studies of dynamics lead to an excess of masses in stellar systems, which should be taken into account in further studies.

The more accurate the input data, the more reliable the orbit. We determine the errors of each orbital parameter by the total influence of the errors of all initial parameters. Since this effect is asymmetric with respect to the obtained solution, we present two errors that correspond to the maximum and minimum values of the given orbital element. The sum of the masses of the components is both the initial and the refined parameter, it is functionally related to parallax, so we fix it.

The main advantage of this method is that it is possible to control the quality of the solution obtained, because to determine the apparent movement parameters, we do not use all available observations, but only the basis. You can also check the consistency of the source data with each other. This fundamentally distinguishes it from methods where the main criterion is agreement with positional observations, which always make it possible to obtain an orbit, but work poorly on a short arc.

Naturally, the AMP-method has limitations, and its application requires an individual ap-

proach. First of all, the impossibility of reconciling all the initial data is due to the fact that the internal subsystems can distort the AMPs, as well as the accepted stellar masses. In this case, the method must not be applied.

In those cases when it is possible to obtain an orbit by the AMP- method, it is currently more correct than other orbits, since it is based on a whole complex of observation results of both an astrometric and astrophysical nature.

2 Results

The purpose of this work is to summarize many years of work, to systematize the results obtained earlier and to add new orbits.

We revised all orbits obtained over 40 years, compared its with modern observations from the WDS catalog, with CCD observations on a 26-inch refractor in Pulkovo for 2003-2019 (Izmailov et al., 2010; Izmailov, Roshchina, 2016; Izmailov et al., 2020) and with the relative positions and motions calculated by us from high-precision data from the Gaia DR2 (Gaia Collaboration et al., 2018).

Most of the objects of our study have separations from $3''$ to $39''$, except for a few closer binaries that are not included in the Pulkovo Observatory observational program, and wider pairs. Basically, these are dwarfs of spectral types F, G and K from the nearest vicinity of the Sun. A total of 67 pairs included in 64 visual binary and multiple systems were considered. Among them are three visual triples (ADS 48 ABF, ADS 7034 ABC, and ADS 10288 ABC), for which we have determined both inner and outer orbits. An unambiguous AMP-solution was obtained for 33 pairs, 2 solutions for 14 pairs, 4 solutions for 3 pairs, families of AMP-orbits were calculated for 17 pairs.

For 29 stars, the orbits have been improved. Most often, the improvement consisted in using a more accurate parallax from the Gaia DR2 catalog and a homogeneous series of Pulkovo CCD observations instead of heterogeneous ones. In this paper, we also publish the orbits ADS 895 and HIP 12706 obtained for the first time. Orbits of 16 stars were completely recalculated from the Gaia DR2 data (positions, proper motions, parallaxes and radial velocities), and the first orbits of seven stars were obtained.

In 20 out of 67 cases, the quasi-instantaneous motion according to the Gaia DR2 data contradicts the average motion according to all-world observations. This is grounds for suspecting the presence of an additional satellite. Therefore to improve our orbits we used only Gaia DR2 parallaxes, new data from the literature, and elongated Pulkovo series. See, for example, (Shakht et al., 2020; Romanenko, Izmailov, 2021; Kiyeva et al., 2021).

On the other hand, 24 pairs are known to have confirmed inner subsystems. Usually, short-period spectral satellites did not affect the AMP-values, and only increased their errors. The satellite's motion was taken into account when calculating the outer orbit, where it possible.

The results are presented [on the website izmccd.puldb](#) in the form of spreadsheets and an Appendix, which includes comments on each star and graphs illustrating the comparison of ephemeris with observations, as well as the region of stable solutions for families.

Here we give only Table 1, which presents data characterizing the components of the stellar pairs studied, series of observations and obtained solutions for each star.

Designations: Columns 1-3 give numbers of pairs (1 — in order, 2 — according to the Hipparcos catalog (ESA SP-1200, 1997), 3 — according to the ADS catalog (Aitken, Doolittle,

Note: * — ADS 7251 B = HIP 120005. Designations are given in the text. The last column contains a link to the article in which this orbit was obtained ([0] — if in this article; [1]= (Kiyaveva et al., 2017); [2]= (Kiyaveva et al., 2020); [3]= (Kiyaveva et al., 2001); [4]= (Romanenko, Izmailov, 2021); [5]= (Kiyaveva, Izmailov, 2018); [6]= (Shakht

1932)), column 4 gives the components designations, 5 is the WDS number (Mason et al., 2016), 6–9 are the magnitudes and spectral types of the components according to WDS, 10 and 11 are the spectral types of the components estimated by us according to the effective temperature T_{eff} from the Gaia DR2 data (Gaia Collaboration et al., 2018) and monograph (Agekian, 1981) under the assumption that this component is a dwarf (otherwise, the result is given in parentheses); 12 and 13 are the beginning and end of all WDS observations (version of 2016), 14 is the total number of observations in the WDS, 15 and 16 are the beginning and end of Pulkovo observations, 17 is the number of Pulkovo photographic observations, 18 is the number of Pulkovo CCD observations, 19 is the number of AMP-orbits (k0) or F — family, 20 is code of one letter each: M is the presence of an inner subsystem (in brackets, if the satellite is assumed by us, but not yet confirmed), V is the presence of the radial velocity from observations, C is the presence of the radius of curvature from the observations of the basis (in parentheses, if over the entire arc, but not determined from the short basis), W is a wide pair ($a > 100$ au), O is AMP-orbit improved by the ORBITX program (Tokovinin, 1992), G is AMPs of the final chosen orbit calculated from observations and proper motions of Gaia DR2; column 21 is a reference to the article in which this orbit was obtained.

Note that photographic observations with the 26-inch refractor at Pulkovo ended in 2007 and CCD observations began in 1996, but in this work we have used only systematic CCD observations since 2003 to 2019.

Table 2 presents the initial data for obtaining the AMP-orbit. Namely: the apparent motion parameters and additional parameters, as well as their errors.

Table 3 lists the orbital elements for 50 pairs, their errors depending on the initial parameters, as well as the orientation of the obtained orbits in the galactic coordinate system and the average-weight values (O-C), corresponding to the entire series and to the Gaia DR2 observation. The assignment of weights to observations is explained in the article (Kiyeva et al., 2017). The initial data errors correspond to 1σ , then the orbital elements fall into the specified error range with a probability of 68%.

Table 4 shows the orbital elements for 17 pairs (families) corresponding to singular points, i.e. having a minimum period ($\beta = 0^\circ$), a minimum eccentricity, and limiting periods for reliable orbits of the families.

Here we should note the peculiarity inherent in the algorithm for determining orbits by position and velocity. See the monographs (Subbotin, 1968) and (Kholshchevnikov, Titov, 2007).

First of all, we obtain the semi-major axis of the orbit a according to the energy integral by the formula:

$$\frac{1}{a} = \frac{2}{r} - \frac{v^2}{k^2} \quad (4)$$

For values of β close to β_{max} , when the orbit is close to parabolic, the error in determining a is large. Then calculating the ephemeris from the found orbit, we get an erroneous value of r :

$$r = a(1 - e \cos E) \quad (5)$$

Here e is the eccentricity, E is the eccentric anomaly. In addition to the inaccurate value of a , the value of r is affected by the position that the satellite occupies in orbit at the instant T_0 . It is obvious that a greater uncertainty is obtained near the periastron. In Table 4, we include only reliable solutions when the cycle of calculating the orbit and its ephemeris is closed and all

the orbits of the family fit the observed series well.

In the Appendix ([on the site izmccd.puldb](http://on.the.site/izmccd.puldb)) comments and graphics are given for each star. The comments briefly describe the history of the study of the system and the rationale for this result. The graphs show series of observations, orbit ephemeris, and the direction of motion according to Gaia DR2 data at the instant of 2015.5.

The following dependences are presented: $\rho(t)$, $\theta(t)$ and $y(x)$. A graph in the picture plane $y(x)$ is sometimes presented in two forms: a fragment of an arc covered by observations, and a complete orbit during the entire period. Then you can see how small the observed arc is.

For all families, the functional dependence $lg(a) = f(e)$ is additionally presented as a graph and the region of possible influence of the Galaxy is determined. For visual triple stars (ADS 48, ADS 7034 and ADS 10288), the stability region is also determined as it was done in the work (Kiyeva, Romanenko, 2020).

3 Conclusion

The orbits of 67 wide pairs of visual binary and multiple stars included in 64 systems are presented. Orbits were unambiguously obtained for 33 pairs, among them 22 pairs have a semi-major axis of the orbit of more than 100 au. and periods from 600 to 6000 years. For such wide pairs, the AMP- method, in contrast to other methods, makes it possible to obtain more reliable orbits.

For 40 years, each researcher from the group of A.A.Kiselev has been developing his own algorithms for determining the AMP-orbits, corresponding to the features of the objects of interest to him, depending on the available initial data. To achieve research uniformity and ease of use, we have created a single program that, using the data in Table 2 for each pair, calculates orbit elements with errors, orientation, ephemeris, and deviations to observations (Tables 3 and 4, as well as data for graphs). This program can serve as a tool for determining the AMP-orbits of yet unexplored visual binaries of the Pulkovo program as the missing data become available.

Acknowledgments

This article uses catalogs data from the WDS (Mason et al., 2016) and Gaia DR2 (Gaia Collaboration et al., 2018), the authors are grateful to their creators. This work was supported by the Russian Foundation for Basic Research (grant No. 20-02-00563 A).
